#### **Department of Cybernetics**

### **BACHELOR PROJECT ASSIGNMENT**

Student: Pavel Trutman

**Study programme:** Cybernetics and Robotics

Specialisation: Robotics

**Title of Bachelor Project:** Minimal Problem Solver Generator

#### **Guidelines:**

- 1. Review the state of the art in solving the polynomial systems using linear algebra [1, 2] and the automatic generator of the polynomial solvers [3, 4].
- 2. Implement the improvement [4] of [3] into the existing automatic generator of solvers.
- 3. Implement a variation of algorithm [1], review its behavior, and suggest how to take over some of its elements to the automatic generator and implement it.
- 4. Demonstrate the functionality of the new solver generator and compare it with the original solver.

## ZADÁNÍ BAKALÁŘSKÉ PRÁCE

Student: Pavel Trutman

**Studijní program:** Kybernetika a robotika (bakalářský)

Obor: Robotika

Název tématu: Generátor řešení minimálních problémů

#### Pokyny pro vypracování:

- 1. Prozkoumejte současné metody řešení polynomiálních rovnic [1, 2] a automatický generátor postupu řešení [3, 4].
- 2. Implementujte vylepšení [4] generátoru [3] do existujícího generátoru postupů řešení.
- 3. Implementujte variaci algoritmu [1], experimentujte s jeho chováním a navrhněte, co převzít z [1] do implementace generátoru a implementujte to.
- 4. Demonstrujte funkčnost nového generátoru postupu řešení a porovnejte ji se starým generátorem.

# 1 Introduction

Here comes introduction.

## 2 Polynomial system solving

Firstly we review the state of the art algorithms for computing Gröbner basis. Better understanding of these algorithms helps us to integrate them into polynomial solving algorithms based on Gröbner basis computation more efficiently.

### 2.1 Buchberger Algorithm

Buchberger Algorithm [2], which was invented by Bruno Buchberger, was the first algorithm for computing Gröbner basis. The algorithm is described in details in [1, 4].

#### 2.1.1 First implementation

The first and easy, but very inefficient implementation of the Buchberger Algorithm, Algorithm 1, is based on the observation that we can extend a set F of polynomials to a Gröbner basis only by adding all non-zero remainders  $\overline{S(f_i, f_j)}^F$  of all pairs from F into F until there is no non-zero remainder generated.

The main disadvantage of this simple algorithm is that so constructed Gröbner basis are often bigger than necessary. This implementation of the algorithm is also very inefficient because many of the S-polynomials that are constructed from the critical pairs are reduced to zero so after spending effort on computing them, there is nothing to add to the Gröbner basis G. How to decide which pairs need not be generated is described next.

#### Algorithm 1 Simple Buchberger Algorithm

#### Input:

F a finite set of polynomials

#### **Output:**

G a finite set of polynomials

```
1: G \leftarrow F
 2: B \leftarrow \{\{g_1, g_2\} \mid g_1, g_2 \in G, g_1 \neq g_2\}
 3: while B \neq \emptyset do
           select \{g_1, g_2\} from B
           B \leftarrow B \setminus \{\{g_1, g_2\}\}\
 5:
           h \leftarrow S(g_1, g_2) \\ h_0 \leftarrow \overline{h}^G
 6:
 7:
           if h_0 \neq 0 then
 8:
                 B \leftarrow B \cup \{\{g, h_0\} \mid g \in G\}
 9:
                 G \leftarrow G \cup \{h_0\}
10:
           end if
11:
12: end while
13: return G
```

#### 2.1.2 Improved Buchberger Algorithm

The combinatorial complexity of the simple implementation of the Buchberger Algorithm can be reduced by testing out certain S-polynomials which need not be considered. To know which pairs can be deleted without treatment, we use the first and the second Buchberger's criterion [1]. Sometimes, we can even delete certain polynomials from the set G completely, knowing that every critical pair they will generate will reduce to zero and hence these polynomials themselves will be superfluous in the output set. In the next few paragraphs we will describe the implementation of the Improved Buchberger Algorithm, and of the function Update, which deletes the superfluous polynomials from G according to Gebauer and Möller [8].

The Improved Buchberger Algorithm, Algorithm 2, has the same structure as the Simple Algorithm. The function Update is used at the beginning of the Improved Buchberger Algorithm to initialize the set B of critical pairs and the Gröbner basis G from the input set F of polynomials and at every moment when a new non-zero polynomial  $h_0 = \overline{h}^G$  of an S-polynomial h has been found and the sets B and G are about to be updated.

#### Algorithm 2 Improved Buchberger Algorithm

```
Input:
     F a finite set of polynomials
Output:
     G a finite set of polynomials
 1: G \leftarrow \emptyset
 2: B \leftarrow \emptyset
 3: while F \neq \emptyset do
          select f from F
 4:
          F \leftarrow F \setminus \{f\}
 5:
          (G,B) \leftarrow Update(G,B,f)
 6:
 7: end while
     while B \neq \emptyset do
          select \{g_1, g_2\} from B
 9:
          B \leftarrow B \setminus \{\{g_1, g_2\}\}\
10:
          h \leftarrow S(g_1, g_2)
11:
          h_0 \leftarrow \overline{h}^G
12:
          if h_0 \neq 0 then
13:
              (G,B) \leftarrow Update(G,B,h_0)
14:
          end if
15:
16: end while
17: return G
```

Now, let us look at the function Update, Algorithm 3. First, it makes pairs from the new polynomial h and all polynomials from the set  $G_{old}$  and puts them into the set C. The first while loop (lines 3-9) iterates over all pairs in the set C. In each iteration it select a pair  $\{h, g_1\}$  from the set C and removes it from the set. Then, it looks for another pair  $\{h, g_2\}$  from the set C or the set D. If there is no pair  $\{h, g_2\}$  such that  $(h, g_2, g_1)$  is a Buchberger triple, then the pair  $\{h, g_1\}$  is put into the set D. The triple

 $(h, g_2, g_1)$  of polynomials  $h, g_1$  and  $g_2$  is a Buchberger triple if the equivalent conditions

$$LM(g_2) \mid lcm(LM(h), LM(g_1))$$
 (2.1)

$$\operatorname{lcm}(\operatorname{LM}(h), \operatorname{LM}(g_2)) \mid \operatorname{lcm}(\operatorname{LM}(h), \operatorname{LM}(g_1)) \tag{2.2}$$

$$\operatorname{lcm}(\operatorname{LM}(g_2), \operatorname{LM}(g_1)) \mid \operatorname{lcm}(\operatorname{LM}(h), \operatorname{LM}(g_1)) \tag{2.3}$$

are satisfied. From the second Buchberger's criterion, we know that if a Buchberger triple  $(h, g_2, g_1)$  shows up in the Buchberger Algorithm and the pairs  $\{g_1, g_2\}$  and  $\{h, g_2\}$  are amongs the critical pairs, then the pair  $\{h, g_1\}$  need not be generated. That means that such a pair is not moved from the set C to the set D but it is only removed from the set C. Moreover, this while loop keeps all pairs  $\{h, g_1\}$  where LM(h) and  $LM(g_1)$  are disjoint, i.e. LM(h) and  $LM(g_1)$  have no variable in common, even if the pairs could be removed. The reason of this is that if two or more pairs in C have the same lcm of their leading monomials, then there is a choice which one should be deleted. So we keep the pair where the leading monomials are disjoint. Pairs with disjoint leading monomials are removed in the second while loop, so we eventually remove them all.

The second while loop (lines 11-17) eliminates all pairs with disjoint leading monomials. We can remove such pairs thanks to the first Buchberger's criterion. All remaining pairs are stored in the set E.

The third while loop (lines 19-25) eliminates pairs  $\{g_1,g_2\}$  where  $(g_1,h,g_2)$  is a Buchberger triple from the set  $B_{old}$ . Then the updated set of the old pairs and the new pairs are united into the set  $B_{new}$ .

Finally, the last while loop (lines 28-34) removes all polynomials g whose leading monomial is a multiple of the leading monomial of h from the set  $G_{old}$ . We can eliminate such polynomials for two reasons. Firstly,  $LM(h) \mid LM(g)$  implies  $LM(h) \mid lcm(LM(g), LM(f))$  for arbitrary polynomial f. We can see that (g, h, f) is a Buchberger triple for any f which in future appears in the set G. Moreover, polynomial g will not be missed at the end because in the Gröbner basis G, polynomials with leading monomials that are multiples of leading monomials of another polynomial from G are superfluous, i.e. they will be eliminated in the reduced Gröbner basis.

In the end of the function, the polynomial h is added into the Gröbner basis  $G_{new}$ . The output of the function Update is the Gröbner basis  $G_{new}$  and the set  $B_{new}$  of critical pairs.

## 2.2 $F_4$ Algorithm

The  $F_4$  Algorithm [6] by Jean-Charles Faugère is an improved version of the Buchberger's Algorithm. The  $F_4$  replaces the classical polynomial reduction found in the Buchberger's Algorithm by a simultaneous reduction of several polynomials. This reduction mechanism is achieved by a symbolic precomputation followed by Gaussian elimination implemented using sparse linear algebra methods.  $F_4$  speeds up the reduction step by exchanging multiple polynomial divisions for row-reduction of a single matrix.

#### **2.2.1** Improved Algorithm $F_4$

The main function of the  $F_4$  Algorithm, Algorithm 4, consists of two parts. The goal of the first part is to initialize the whole algorithm.

#### Algorithm 3 Update

```
Input:
      G_{old} a finite set of polynomials
      B_{old} a finite set of pairs of polynomials
      h a polynomial such that h \neq 0
Output:
      G_{new} a finite set of polynomials
      B_{new} a finite set of pairs of polynomials
  1: C \leftarrow \{\{h,g\} \mid g \in G_{old}\}
 2: D \leftarrow \emptyset
 3: while C \neq \emptyset do
           select \{h, g_1\} from C
 4:
 5:
           C \leftarrow C \setminus \{\{h, g_1\}\}\}
           if LM(h) and LM(g_1) are disjoint or
 6:
                     (\operatorname{lcm}(\operatorname{LM}(h), \operatorname{LM}(g_2)) \nmid \operatorname{lcm}(\operatorname{LM}(h), \operatorname{LM}(g_1)) \text{ for all } \{h, g_2\} \in C \text{ and }
                     \operatorname{lcm}(\operatorname{LM}(h), \operatorname{LM}(g_2)) \nmid \operatorname{lcm}(\operatorname{LM}(h), \operatorname{LM}(g_1)) for all \{h, g_2\} \in D) then
                 D \leftarrow D \cup \{\{h, g_1\}\}\
 7:
           end if
 8:
 9: end while
10: E \leftarrow \emptyset
11: while D \neq \emptyset do
           select \{h, g\} from D
12:
           D \leftarrow D \setminus \{\{h,g\}\}\}
13:
14:
           if LM(h) and LM(g) are not disjoint then
                 E \leftarrow E \cup \{\{h,g\}\}
15:
           end if
16:
17: end while
18: B_{new} \leftarrow \emptyset
      while B_{old} \neq \emptyset do
           select \{g_1, g_2\} from B_{old}
20:
21:
            B_{old} \leftarrow B_{old} \setminus \{\{g_1, g_2\}\}\
22:
           if LM(h) \nmid lcm(LM(g_1), LM(g_2)) or
                     \operatorname{lcm}(\operatorname{LM}(g_1), \operatorname{LM}(h)) = \operatorname{lcm}(\operatorname{LM}(g_1), \operatorname{LM}(g_2)) or
                     \operatorname{lcm}(\operatorname{LM}(h), \operatorname{LM}(g_2)) = \operatorname{lcm}(\operatorname{LM}(g_1), \operatorname{LM}(g_2)) then
23:
                 B_{new} \leftarrow B_{new} \cup \{\{g_1, g_2\}\}\
           end if
24:
25: end while
26: B_{new} \leftarrow B_{new} \cup E
27: G_{new} \leftarrow \emptyset
28: while G_{old} \neq \emptyset do
           select g from G_{old}
29:
           G_{old} \leftarrow G_{old} \setminus \{g\}
30:
           if LM(h) \nmid LM(g) then
31:
                 G_{new} \leftarrow G_{new} \cup \{g\}
32:
33:
           end if
34: end while
35: G_{new} \leftarrow G_{new} \cup \{h\}
36: return (G_{new}, B_{new})
```

First, it generates the set P of critical pairs and initializes the Gröbner basis G. This is done by taking each polynomial from the input set F and calling the function Update on it, which updates the set P of pairs and the set G of basic polynomials.

The second part of the algorithm generates new polynomials and adds them into the set G. In each iteration, it selects some pairs from P using the function Sel. Many selection strategies are possible and it is still an open question how to best select the pairs [6]. Some selection strategies are described in the section 2.2.6 on page 11. Then, it splits each selected pair  $\{f_1, f_2\}$  into two tuples. The first tuple contains the first polynomial  $f_1$  of the pair and the monomial  $m_1$  such that  $LM(m_1f_1) = lcm(LM(f_1), LM(f_2))$ . The second tuple is constructed in the same way from the second polynomial  $f_2$  of the pair. All tuples from all selected pairs are put into the set L, i.e. duplicates are removed.

Next, function Reduction is called on the set L. It stores its result in the set  $\tilde{F}^+$ . In the end of the algorithm it iterates through all new polynomials in the set  $\tilde{F}^+$  and calls the function Update on each of them. This generates new pairs into the set P of critical pairs and extends the Gröbner basis G.

This algorithm terminates when the set P of pairs is empty. Then the set G is a Gröbner basis and it is the output of the algorithm.

#### **Algorithm 4** Improved Algorithm $F_4$

```
Input:
```

```
F a finite set of polynomials Sel a function List(Pairs) \to List(Pairs) such that Sel(l) \neq \emptyset if l \neq \emptyset
```

#### Output:

G a finite set of polynomials

```
1: G \leftarrow \emptyset
 2: P \leftarrow \emptyset
 3: d \leftarrow 0
 4: while F \neq \emptyset do
           select f form F
           F \leftarrow F \setminus \{f\}
 6:
 7:
           (G,P) \leftarrow Update(G,P,f)
 8: end while
 9: while P \neq \emptyset do
           d \leftarrow d + 1
10:
           P_d \leftarrow Sel(P)
11:
           P \leftarrow P \backslash P_d
12:
           L_d \leftarrow Left(P_d) \cup Right(P_d)
13:
           (\tilde{F}_d^+, F_d) \leftarrow Reduction(L_d, G, (F_i)_{i=1, \dots, (d-1)})
14:
           for h \in \tilde{F}_d^+ do
15:
                (G, P) \leftarrow Update(G, P, h)
16:
17:
           end for
18: end while
19: \mathbf{return} \ G
```

#### 2.2.2 Function Update

In the  $F_4$  Algorithm, the standard implementation of the Buchberger's Criteria such as the Gebauer and Möller installation [8] is used. Details about the function Update can be found in the section 2.1.2. The pseudocode of the function is shown in Algorithm 3.

#### 2.2.3 Function Reduction

Function *Reduction*, Algorithm 5, performs polynomial division using methods of linear algebra.

The input of the function Reduction is a set L containing tuples of monomial and polynomial. These tuples were constructed in the main function of the  $F_4$  Algorithm from all selected pairs.

First, the function Reduction calls the function  $Symbolic\ Preprocessing$  on the set L. This returns a set F of polynomials to be reduced. To use linear algebra methods to perform polynomial division, the polynomials have to be represented by a matrix. Each column of the matrix corresponds to a monomial. Columns have to be ordered with respect to the monomial ordering used so that the most right column corresponds to "1". Each row of the matrix corresponds to a polynomial from the set F. The matrix is constructed as follows. On the (i,j) position in the matrix, we put the coefficient of the term corresponding to j-th monomial from the i-th polynomial from the set F.

We next reduce the matrix to a row echelon form using, for example, Gauss-Jordan elimination. Note that this matrix is typically sparse so we can use sparse linear algebra methods to save computation time and memory. After elimination, we construct resulting polynomials by multiplying the reduced matrix by a vector of monomials from the right.

In the end, the function returns the set  $\tilde{F}^+$  of reduced polynomials such that their leading monomials are not leading monomials of any polynomial from the set F of polynomials before reduction.

#### Algorithm 5 Reduction

#### Input:

L a finite set of tuples of monomial and polynomial

G a finite set of polynomials

 $\mathcal{F} = (F_i)_{i=1,\dots,(d-1)}$ , where  $F_i$  is finite set of polynomials

#### **Output:**

 $\tilde{F}^+$  a finite set of polynomials

F a finite set of polynomials

```
1: F \leftarrow Symbolic\ Preprocessing(L, G, \mathcal{F})
2: \tilde{F} \leftarrow \text{Reduction to a Row Echelon Form of } F
3: \tilde{F}^+ \leftarrow \left\{ f \in \tilde{F} \mid \text{LM}(f) \notin \text{LM}(F) \right\}
```

4: **return**  $(\tilde{F}^+, F)$ 

#### 2.2.4 Function Symbolic Preprocessing

Function Symbolic Preprocessing, Algorithm 6, starts with a set L of tuples, each containing a monomial and a polynomial. These tuples were constructed in the main

function of the  $F_4$  Algorithm from the selected pairs. Then, the tuples are simplified by the function Simplify and, after multiplying polynomials with corresponding monomials, the results are put into the set F.

Next, the function goes through all monomials in the set F and for each monomial m looks for some polynomial f from the Gröbner basis G such  $m = m' \cdot LM(f)$  where m' is some monomial. All such polynomials f and monomials m' are, after simplification, multiplied and put into the set F. The goal of this search is to have for every monomial in F a polynomial in F with the same leading monomial. This will ensure that all polynomials from F will be reduced for G after polynomial division by linear algebra.

#### Algorithm 6 Symbolic Preprocessing

```
Input:
    L a finite set of tuples of monomial and polynomial
    G a finite set of polynomials
    \mathcal{F} = (F_i)_{i=1,\dots,(d-1)}, where F_i is finite set of polynomials
Output:
    F a finite set of polynomials
 1: F \leftarrow \{multiply(Simplify(m, f, \mathcal{F})) \mid (m, f) \in L\}
 2: Done \leftarrow LM(F)
 3: while M(F) \neq Done do
 4:
        m an element of M(F) \setminus Done
        Done \leftarrow Done \cup \{m\}
 5:
        if m is top reducible modulo G then
 6:
            m = m' \cdot LM(f) for some f \in G and some monomial m'
 7:
            F \leftarrow F \cup \{multiply(Simplify(m', f, \mathcal{F}))\}
 8:
        end if
 9:
10: end while
```

#### 2.2.5 Function Simplify

11: return F

The function Simplify, Algorithm 7, simplifies a polynomial mf which is a product of a given monomial m and a polynomial f.

The function recursively looks for a monomial m' and a polynomial f' such that LM(m'f') = LM(mf). The polynomial f' is selected from all polynomials that have been reduced in previous iterations (sets  $\tilde{F}$ ). We select polynomial f' such that the total degree of m' is minimal.

This is done in the function  $Symbolic\ Preprocessing$  to insert polynomials that are mostly reduced and have a small number of monomials into the set F of polynomials to be reduced. This, of course, speeds up the following reduction.

#### 2.2.6 Selection strategy

For the speed of the  $F_4$  Algorithm, it is very important how the critical pairs from the list of all critical pairs P are selected in each iteration. This depends on the implementation of the function Sel. There are more possible selection strategies:

• The easiest implementation is to select all pairs from *P*. In this case we reduce all critical pairs at the same time.

#### Algorithm 7 Simplify

```
Input:
    m a monomial
    f a polynomial
    \mathcal{F} = (F_i)_{i=1,\dots,(d-1)}, where F_i is finite set of polynomials
Output:
    (m', f') a non evaluated product of a monomial and a polynomial
 1: for u \in \text{list of all divisors of } m \text{ do}
        if \exists j \ (1 \leq j \leq d) such that (uf) \in F_j then
 2:
            F_j is the Row Echelon Form of F_j
 3:
            there exists a (unique) p \in \tilde{F}_i such that LM(p) = LM(uf)
 4:
            if u \neq m then
 5:
                return Simplify(\frac{m}{u}, p, \mathcal{F})
 6:
 7:
            else
                return (1, p)
 8:
            end if
 9:
        end if
10:
11: end for
12: return (m, f)
```

- If the function Sel selects only one critical pair then the  $F_4$  Algorithm is the Buchberger Algorithm. In this case the Sel function corresponds to the selection strategy in the Buchberger Algorithm.
- The best function that Faugère has tested is to select all critical pairs with a minimal total degree. Faugère calls this strategy the *normal strategy for*  $F_4$ . Pseudocode of this function can be found as Algorithm 8.

```
Algorithm 8 Sel – The normal strategy for F_4
```

```
Input:

P a list of critical pairs

Output:

P_d a list of critical pairs

1: d \leftarrow min \{ deg(lcm(p)) \mid p \in P \}

2: P_d \leftarrow \{ p \in P \mid deg(lcm(p)) = d \}

3: return P_d
```

## 2.3 $F_5$ Algorithm

Since in the Buchberger Algorithm or in the  $F_4$  Algorithm we spend much computation time to compute S-polynomials which will reduce to zero, the  $F_5$  Algorithm [7] by Jean-Charles Faugère was proposed to eliminate these reductions to zero. The  $F_5$  Algorithm saves computation time by removing useless critical pairs which will reduce to zero. The syzygies [4] are used to recognize useless critical pairs in advance.

There are several approaches how to use syzygies to remove useless pairs. For example the idea of [13] is to compute a basis of the module of syzygies together with the

computing of the Gröbner basis of the given polynomial system. Then a critical pair can be removed if the corresponding syzygy is a linear combination of the elements of the basis of syzygies.

The strategy of the  $F_5$  Algorithm is to consider only principal syzygies without computing the basis of the syzygies. The principal syzygy is a syzygy such that  $f_i f_j - f_j f_i = 0$  where  $f_i$  and  $f_j$  are polynomials. This restriction implies that not all useless critical pairs have to be removed so a reduction to zero can still appear later. However it was proved that if the input system is a regular sequence then there is no reduction to zero.

To show how to distinguish which pairs need not be considered, we use the example taken from [7]. Consider polynomials  $f_1$ ,  $f_2$  and  $f_3$ . Then, the principal syzygies  $f_i f_j - f_j f_i = 0$  can be written as follows:

$$u(f_2f_1 - f_1f_2) + v(f_3f_1 - f_1f_3) + w(f_2f_3 - f_3f_2) = 0 (2.4)$$

where u, v and w are arbitrary polynomials. This can be also rewritten as

$$(uf_2 + vf_3)f_1 - uf_1f_2 - vf_1f_3 + wf_2f_3 - wf_3f_2 = 0. (2.5)$$

We can see that all relations  $hf_1$  are such that h is in the ideal generated by polynomials  $f_2$  and  $f_3$ . So if we have computed Gröbner basis of the polynomials  $f_2$  and  $f_3$ , it is easy to decide which new generated polynomials can be removed. We can remove all polynomials in the form  $tf_1$  such that t is a term divisible by leading monomial of an element of the ideal generated by  $f_2$  and  $f_3$ . Therefore the  $F_5$  Algorithm is an incremental algorithm so if we have polynomials  $f_1, \ldots, f_m$  on the input we have to compute all Gröbner basis of the following ideals:  $(f_m), (f_{m-1}, f_m), \ldots, (f_1, \ldots, f_m)$  in this order.

Many reviews, implementations and modifications of the  $F_5$  Algorithm have been made. Let us emphasize some of them. The first implementation of the  $F_5$  was made by Jean-Charles Faugère himself in the language C. Then there is an implementation in Magma by A. J. M. Segers [17]. Another review and implementation in Magma was done by Till Stegers [18]. Since there is no proof of termination of the  $F_5$  Algorithm, a modification [5] has been introduced such that it always terminates.

## 3 Automatic generator

The automatic generator of Gröbner basis solvers is used to easily solve problems leading to systems of polynomial equations. These systems usually arise when solving minimal problems [16] in computer vision. Typically, these systems are not trivial so special solvers have to be designed for concrete problems to achieve efficient and numerically stable solvers. But solvers generated for concrete problems can not be easily applied for similar or new problems and therefore the automatic generator was proposed in [12]. Solvers generated by the automatic generator can be easily used to solve complex problems even by non-experts users.

The input of the automatic generator is a system of polynomial equations with a finite number of solutions and the output is a MATLAB or a Maple code that computes solutions of the given system for arbitary coefficients. One of the goals of this thesis is to improve previous implementation [12] of the automatic generator to construct more efficient and numerically stable solvers.

The newest version of the automatic genenerator implemented in MATLAB can be downloaded from [15].

### 3.1 Description of the automatic generator

In this section we would like to briefly describe the procedure for generating solvers. The procedure is based on computation of the action matrix from which solutions can be obtained. The automatic generator consists of several independent modules, see Figure 3.1. Since all these modules are independent, they can be easily improved or replaced by more efficient implementations. Next we describe each of these modules, full description can be found in [12, 10].

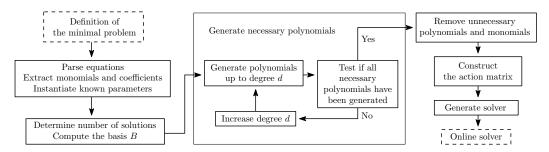

Figure 3.1 Block diagram of the automatic generator

#### 3.1.1 Definition of the minimal problem

Definitions of minimal problems to be solved are given in separate functions that are stored in the folder minimalProblems. Each of the definitions has to contain the necessary information about the minimal problem. First of all, the system of polynomial equations with symbolic variables and parameters has to be provided. Next, we have to specify the list of unknown variables and known parameters. Optionally, if we know the monomial basis B of the polynomial system in advance, we can specify it to save

some computation time. The monomial basis B is a set  $\{m \mid \overline{m}^G = m\}$  where m is a monomial and G is the Gröbner basis of the given polynomial system. At last we have to set some settings for the automatic generator. We recommend to obtain the default settings by calling the function  $gbs\_InitConfig()$  and only overwrite the settings we want to change. In the folder minimalProblem, there are some examples which are self explanatory and can be used as templates to create new minimal problem definitions.

#### 3.1.2 Equations parser, instantiating

In the next step, we have to parse the given equations, which means that we extract monomials and parameters used and obtain total degrees of the polynomials. Then, we instantiate each known parameter with a random number from  $\mathbb{Z}_p$ . We assign a unique identifier to each parameter used. The reason is that we need to track the parameters through the process of manipulating with the polynomials in order to be able to restore the process in the solver generation module.

#### 3.1.3 Monomial basis B computation

We need to know the monomials basis B to recognize when we have generated all polynomials that are necessary to build the action matrix. If the basis B was not provided within the definition of the minimal problem, we have to compute it by ourselves. Because there is no function or simple script to compute the basis in MATLAB we have to do it by calling an external software.

The easiest solution to implement was to use the Maple toolbox for MATLAB. This enables us to call Maple functions from the MATLAB environment directly. To use this option we have to set cfg.GBSolver = @gbs\_findAlgB\_maple in the settings of the automatic generator. Unfortunately it shows up that the Maple toolbox for MATLAB in not compatible with the MATLAB Symbolic Math Toolbox in versions newer than R2008 so we do not recommend to use this option nowadays, but the option is still available on older computers.

The second implemented option is to use the algebraic geometry software Macaulay2 [9]. In the folder gbsMacaulay there is a template code\_template.m2 into which we simply write the given polynomial system. This updated file is saved as code.m2 which is executed by Macaulay2 and the results are parsed back in MATLAB. To set up this option we need to install the software Macaulay2 and set cfg.GBSolver = Qgbs\_findAlgB\_macaulay in the automatic generator settings. A problem could be that the Macaulay2 is not easy to set up under the Windows OS. Therefore, the installation file of Macaulay2 is provided within the automatic generator. The only thing that has to be done is to edit the file calc.bat in the folder gbsMacaulay and follow the instructions in the file.

Because of the modularity of the generator, this part can be replaced by another function computing the monomial basis B.

The last option is to compute the basis B in advance and set it into the definition of the minimal problem.

In the end, we have to check the number of solutions of the given polynomial system. If there is a finite number of solutions we can continue with the computation.

#### 3.1.4 Polynomial generator

To be able to build the action matrix, we have to generate enough polynomials such that after their reduction we get polynomials  $q_i$  which have leading monomials from

the set  $(x_k \cdot B) \setminus B$  where  $x_k$  is a variable and all remaining monomials of  $q_i$  are from the set B. That is the reason why we had to compute the basis B in the previous step.

In this part of the automatic generator, we represent polynomials as row vectors so that systems of polynomials can be represented by matrices. This representation enables us to easily multiply polynomials with monomials only by shifting the coefficients in the vectors or to reduce the whole polynomial systems by performing the Gauss-Jordan eliminations on the corresponding matrices.

Let  $f_i \in F$  where F is a set of polynomials from the input. Let maxdeg is a maximal total degree of all polynomials  $f_i$ . At the beginning we put all polynomials  $\{mf_i \mid f_i \in F; \deg(mf_i) = \deg(f_i), \ldots, maxdeg\}$  into the matrix M, where m is a monomial. Now we perform the Gauss-Jordan elimination on the matrix M and save the result as matrix  $\tilde{M}$ . Then we check if there exists a variable  $x_k$  for which all required polynomials  $q_i$  are present in  $\tilde{M}$ . If we find such a variable we can continue with the construction of the action matrix for the variable. If not, we have to add more polynomials to the matrix M. We increment maxdeg by one and add all polynomials  $\{mf_i \mid f_i \in F; \deg(mf_i) = maxdeg\}$  to the matrix M. Then we continue with the elimination and with the checking the action matrix requirements as explained above. We repeat these steps until all required polynomials  $q_i$  are generated so the action matrix can be built. The pseudocode of this process is shown in Algorithm 9. The function Check Action Matrix Conditions from this code checks if all polynomials  $q_i$  are generated in  $\tilde{M}$  for at least one variable from the given list of variables. If such a variable is found, the function returns it, otherwise it returns an empty set.

#### **Algorithm 9** Polynomial generator – One elimination solver

#### Input:

```
F a set of polynomials variables a list of variables alg B a monomial basis B
```

#### Output:

 $\tilde{M}$  a matrix representing a set of polynomials var a variable

```
1: maxdeg \leftarrow \max\{\deg(f_i) \mid f_i \in F\}

2: M \leftarrow \{mf_i \mid f_i \in F; \deg(mf_i) = \deg(f_i), \ldots, maxdeg; m \text{ is a monomial}\}

3: \tilde{M} \leftarrow \text{Reduction to a Row Echelon Form of } M

4: var \leftarrow Check \ Action \ Matrix \ Conditions(\tilde{M}, variables, algB)

5: \mathbf{while} \ var = \emptyset \ \mathbf{do}

6: maxdeg \leftarrow maxdeg + 1

7: M \leftarrow M \cup \{mf_i \mid f_i \in F; \deg(mf_i) = maxdeg; m \text{ is a monomial}\}

8: \tilde{M} \leftarrow \text{Reduction to a Row Echelon Form of } M

9: var \leftarrow Check \ Action \ Matrix \ Conditions(\tilde{M}, variables, algB)

10: \mathbf{end \ while}

11: \mathbf{return} \ (\tilde{M}, var)
```

In this whole process we need to keep track how the matrix M was built. Recall that each coefficient of the polynomials  $f_i$  has a unique identifier assigned to it in the equations parser. Because the whole matrix M contains only the polynomials  $f_i$  or their multiples with monomials, only the coefficients from the polynomials  $f_i$  appear in the matrix M. We just have to keep the positions of the coefficients. This is done by matrix  $\hat{M}$ . The matrix  $\hat{M}$  is built at the same time as the matrix M by this way. When

we put a coefficient into the matrix M, we also put the corresponding indentifier to the matrix  $\hat{M}$  at the same possition. The matrix  $\hat{M}$  enables us to recover the process of polynomial generation in the code generator module.

#### 3.1.5 Removing unnecessary polynomials and monomials

Since the polynomials were generated systematically in the previous step there may appear some polynomials which are not necessary for the constructing of the action matrix. The goal of this part of the automatic generator is to remove as many as possible polynomials which are not necessary.

We can remove a polynomial r from the matrix M if the corresponding eliminated matrix  $\tilde{M}$  still contains all required polynomials  $q_i$ . In this way we try to remove all polynomials from M.

Because the success of removing a polynomial depends on the previous removals, the number of removed polynomials depends on the ordering in which the polynomials are removed. In the automatic generator we start removing polynomials from the one with the largest leading monomial by monomial ordering used. Because it is very inefficient to remove polynomials one by one and perform each time an expensive Gauss-Jordan elimination, we can enhance the procedure by trying to remove more polynomials at the time. In the automatic generator, this heuristic is used. If we have successfully removed k polynomials, we try to remove 2k polynomials in the next step. If the removal of k polynomials have failed, we try to remove  $\frac{1}{4}k$  polynomials in the next step. The pseudocode of this removing process is shown as Algorithm 10.

Moreover we can reduce the size of the matrix M by removing unnecessary monomials. A monomial is unnecessary when its removal does not affect the building of the action matrix. We have to keep all monomials such that they are leading monomials of polynominals in the corresponding matrix  $\tilde{M}$  and all monomials that are present in the basis B. All other monomials can be removed. If we remove all such unnecessary monomials then the matrix M will have dimensions  $n \times (n+N)$  where n is the number of the polynomials in the matrix M and N is the number of solutions of the given system.

#### 3.1.6 Construction of the action matrix

This part of the automatic generator starts with the eliminated matrix  $\tilde{M}$  of polynomials and variable  $x_k$  for which all required polynomials  $q_i$  are present in  $\tilde{M}$ .

Let us describe the construction of the action matrix in an informal and practical way rather than by using the theory. If the theory is needed, it can be found in [10]. The action matrix  $M_{x_k}$  corresponding to the variable  $x_k$  is a square matrix of dimensions  $N \times N$  where N is the number of elements of the monomial basis B. Each row and column of  $M_{x_k}$  corresponds to a monomial  $b_i \in B$ . Let the monomials  $b_i$  be sorted such that if  $b_l \prec b_k$  then k < l where  $\prec$  is the monomial ordering used. We put coefficients of the polynomial  $m_i = \overline{(x_k b_i)}^F$  to the i-th row where F are polynomials corresponding to  $\tilde{M}$ . Because  $\tilde{M}$  is in a row echelon form there are two possibilities how the i-th row can be constructed:

- 1.  $x_k b_i = b_j$  for some  $b_j \in B$ . That means that  $x_k b_i$  is irreducible by F and  $m_i$  is a monomial in B. In this case we set  $M_{x_k}(i,j) = 1$  and  $M_{x_k}(i,k) = 0$  where  $k \neq j$ .
- 2.  $x_k b_i \neq b_j$  for all  $b_j \in B$ .

#### Algorithm 10 Remove unnecessary polynomials

#### Input:

```
M a matrix representing a set of polynomials variable a variable algB a monomial basis B
```

#### Output:

M a matrix representing a set of polynomials

```
1: rows \leftarrow number of rows of M
 2: step \leftarrow \max\{|rows/32|, 1\}
 3: up \leftarrow 1
 4: filter \leftarrow \{1, 2, \dots, rows\}
 5: while up \leq rows do
         down \leftarrow up + step - 1
 6:
         if down > rows then
 7:
             down \leftarrow rows
 8:
             step \leftarrow down - up + 1
 9:
         end if
10:
         filter_{Old} \leftarrow filter
11:
         filter \leftarrow filter \setminus \{up, up + 1, \dots, down\}
12:
         M \leftarrow \text{Reduction to a Row Echelon Form of } M \text{ only with rows specified by } filter
13:
         v \leftarrow Check\ Action\ Matrix\ Conditions(M, variable, alg B)
14:
         if v = variable then
15:
             up \leftarrow down + 1
16:
             step \leftarrow 2step
17:
18:
         else
             if step = 1 then
19:
                 up \leftarrow up + 1
20:
             else
21:
                 step \leftarrow \max\{|step/4|, 1\}
22:
23:
24:
             filter \leftarrow filter_{Old}
         end if
25:
26: end while
27: return M only with rows specified by filter
```

In this case there is f such that  $LM(m_i) = LM(f)$  where  $f \in F$  so  $m_i = x_k b_i - f$ . Since all monomials of f except LM(f) are from B, all monomials of  $m_i$  are also from B. We put coefficient of  $m_i$  at the monomial  $b_j$  to the matrix  $M_{x_k}$  on the (i, j) position.

Now, the solutions of the given system can be easily found by computing right eigenvectors of the action matrix  $M_{x_k}$ .

#### 3.1.7 Solver generator

The last task of the automatic generator is to create a solver which will solve the given polynomial system for an arbitrary set of parameters preserving its structure. The current version of the automatic generator can generate solvers for MATLAB and Maple but new code generators can be easily added. It can be set in the min-

imal problem definition by setting cfg.exportCode which solvers will be generated. For instance to create both MATLAB and Maple solvers we set cfg.exportCode = {'matlab' 'maple'}.

To create a solver we have to restore the process of creation of the matrix M. This process is saved as the matrix  $\hat{M}$  which contains unique identifiers on the positions where the given parameters have to be put. So the matrix M can be built for each given set of parameters. Then the Gauss-Jordan elimination is called on M so we get the matrix  $\tilde{M}$ . Now the action matrix is built in the same way as above and the solutions are extracted from it. To sum up the final solver just creates the matrix M by putting parameters to the correct places. After Gauss-Jordan elimination the action matrix is built by copying some parts of rows of  $\tilde{M}$  and then the solutions are extracted by using the eigenvectors of the action matrix.

#### 3.1.8 Usage

The automatic generator is designed to be used even by non-expert users and to be easily expanded or improved.

At first, the script setpaths.m should be executed from the root directory of the automatic generator. This will add all required paths to the MATLAB environment.

Next we have to set up the definition of the minimal problem we want to solve. How the definition have to be specified is written in the section 3.1.1. All these definitions are stored in the folder minimalProblems. To generate the solver we call the function gbs\_GenerateSolver(MinimalProblem) where MinimalProblem is the name of the definition of the minimal problem, i.e. the name of the function in the folder minimalProblems. This will generate us solver solver MinimalProblem.m for the MATLAB solver and solver\_MinimalProblem.txt for the Maple solver. These solvers are stored in the folder solvers.

For example, let us present generating of a solver for the 6-point focal length problem [14]. We have defined this problem as a function sw6pt.m in the folder minimalProblems. By calling the function gbs\_GenerateSolver('sw6pt') we get solvers solver\_sw6pt.m and solver\_sw6pt.txt in the folder solvers.

### 3.2 Improvements

The bottleneck of the automatic generator is the polynomial generator module. Since the polynomials are generated systematically the matrices in the resultant solvers are often bigger than necessary which means that the solvers are not efficient. So many improvements of the automatic generator [12] can be done. For example if we want to generate multiple elimination solvers as suggested in [10] the polynomial generator module have to be improved or totaly replaced. In the same way some strategies from other algorithms, for example from the  $F_4$  Algorithm [6], can be taken over and implemented into the automatic generator. Because we are mostly working with sparse matrices in the automatic generator the variant of Gauss-Jordan elimination for sparse matrices can be implemented to save some computation time.

#### 3.2.1 Reimplementation

The previous implementation [12] of the automatic generator was implemented in MATLAB R2008. It shows up that new versions of MATLAB are not backward compatible so the automatic generator fails when lauched in some newer version than R2008.

So the first task was to reimplement the old implementation into new version of MAT-LAB. All the changes of the code were minor and just in the implementation level.

One important change is that the Maple Toolbox for MATLAB in not compatible with the MATLAB Symbolic Math Toolbox. One of the options in the monomials basis B module is to use the Maple toolbox to compute the basis B. Because of the incompatibility this option can be used no longer and the algebraic geometry software Macaulay2 [9] have to be used.

The new version of the automatic generator, as it is desribed in this thesis, is compatible with the version R2015 of MATLAB 64-bit and 32-bit under Windows and Unix operation systems.

#### 3.2.2 Multiple elimination solver

In the section 3.1.4 there is desribed the starategy how to generate polynomials for one elimination solvers. But in some cases it may be better to create multiple elimination solvers. A multiple elimination solver is a solver where polynomials are generated systematically by multiplying already generated polynomials by monomials and reduced each time by Gauss-Jordan elimination. So the task of this section is to describe how the polynomial generator of the automatic generator can be improved to be able to generate polynomials for multiple elimination solvers.

In this strategy we generate in each step all polynomials up to degree d and perform a Gauss-Jordan elimination on them. We increase the degree d when no new polynomials can be generated by multiplying already generated polynomials by some monomials. We stop this process when all polynomials  $q_i$  are generated.

This strategy is very usefull especially when we are generating solvers for systems with many variables. The reason is that the increasing of the degree d of generated polynomials leads to a large number of new generated polynomials.

Now let us look on the process of generating polynomials in more details. The pseudocode is shown as Algortihm 11. Let the maxdeg is a maximal total degree of all polynomials from the given system F. At the beginning we put into the matrix  $M_1$  all polynomials up to degree maxdeg such that they are multiples of polynomials from Fand some monomials. We get the matrix  $M_1$  by eliminating the matrix  $M_1$ . We check if there exists a variable for which all polynomials  $q_i$  are generated in  $M_1$ . If no such variable is found we generate new polynomials with higher total degree. We increase the degree maxdeg up to which we are generating polynomials. The variable step tells how much we want to increase the total degree in one step. Into the variable mindeg we save the maxdeq from the previous iteration incremented by one to keep track to which degree we have generated polynomials yet. We build new matrix  $M_2$  from the matrix  $M_1$  and we add all polynomials with total degrees from mindeg to maxdeg. These polynomials are multiples of polynomials from  $M_1$  and some monomials. We save the result of the Gauss-Jordan elimination as the matrix  $M_2$ . We repeat this process until no new polynomials are added in one iteration. That situation happens when two matrices  $M_j$  and  $M_{j-1}$  have same number of non zero rows. In this case we check if all polynomials  $q_i$  are generated for some variable. If not we have to generate new polynomials with higher total degree. If the variable has been found we return the last generated matrix  $M_i$  and the found variable. You may notice that when we are leaving the repeat-until loop on line 13 there are two equivalent matrices  $M_j$  and  $M_{i-1}$ . These matrices have the same non zero rows and differ only with the number of zero rows. This is the reason why we can remove the matrix  $M_i$  by decrementing the variable j on line 14.

#### Algorithm 11 Polynomial generator – Multiple elimination solver

```
Input:
     F a set of polynomials
     variables a list of variables
     algB a monomial basis B
     step an integer
Output:
     M a matrix representing a set of polynomials
     var a variable
 1: maxdeg \leftarrow max\{deg(f_i) \mid f_i \in F\}
 2: j \leftarrow 1
 3: M_1 \leftarrow \{m \times f_i \mid f_i \in F; \deg(m \times f_i) = \deg(f_i), \dots, maxdeg; m \text{ is a monomial}\}
 4: M_1 \leftarrow \text{Reduction to a Row Echelon Form of } M_1
 5: var \leftarrow Check\ Action\ Matrix\ Conditions(M_1, variables, alg B)
 6: while var = \emptyset do
         mindeg \leftarrow maxdeg + 1
 7:
         maxdeg \leftarrow maxdeg + step
 8:
         repeat
 9:
             j \leftarrow j + 1
10:
             M_j \leftarrow \tilde{M}_{j-1} \cup \left\{ m \times f_i \mid f_i \in \tilde{M}_{j-1}; \right.
11:
                    deg(m \times f_i) = mindeg, \dots, maxdeg; m \text{ is a monomial}
             \tilde{M}_i \leftarrow \text{Reduction to a Row Echelon Form of } M_i
12:
         until number of nonzero rows of M_i = number of nonzero rows of M_{i-1}
13:
14:
         var \leftarrow Check\ Action\ Matrix\ Conditions(M_i, variables, algB)
15:
16: end while
17: return (M_i, var)
```

To be able to restore the process of generation of polynomials and generate the code of the solver in the solver generator module we have to keep track how the matrices  $M_j$  were built. Therefore we build a matrix  $\hat{M}_j$  for each matrix  $M_j$ . The first matrix  $\hat{M}_1$  is built in the same way as the matrix  $\hat{M}$  when generating one elimination solver. This matrix contains only the unique identifiers of parameters on positions were real values will be put. Because each matrix  $M_j$  is built from the matrix  $\tilde{M}_{j-1}$ , the matrix  $M_j$  contains only coefficients from the matrix  $\tilde{M}_{j-1}$ . So when a coefficient from (m,n) position from  $\tilde{M}_{j-1}$  is put into  $M_j$  at (k,l) position, the tuple (m,n) is put at the position (k,l) of  $\hat{M}_j$ . So if we have the matrix  $\tilde{M}_{j-1}$  and the matrix  $\hat{M}_j$ , the matrix  $M_j$  can be built easily.

To enable generation of multiple elimination solvers we assign an integer to cfg.PolynomialsGeneratorCfg.GJstep in the settings of the automatic generator. The value of the GJstep has the same meaning as the variable *step* from the Algorithm 11. E.g. by setting GJstep = 1 the generated polynomials will be eliminated each time the total degree of generated polynomials is incremented by 1. If we set GJstep = 0 the one elimination solver will be generated as written in the section 3.1.4.

#### 3.2.3 Removing redundant polynomials

We may notice that there appear matrices  $\tilde{M}_j$  with many zero rows in the process of generation polynomials for multiple elimination solvers. This is caused because there are many dependent rows in the corresponding matrices  $M_j$ . These zero rows in matrices  $\tilde{M}_j$  give us no new information so we want to remove as many as possible rows from the matrices  $M_j$  such that the resulting matrices  $\tilde{M}_j$  will have the same nonzero rows as before the removal and no zero rows.

We know that we can remove the same number of rows from  $M_j$  as it is the number of zero rows in  $\tilde{M}_j$ . But we do not know which rows we should remove. So we try to remove each row r from  $M_j$  and if the number of nonzero rows of  $\tilde{M}_j$  stays the same the removal is successful, if not we have to return the row r back into  $M_j$ . We end this process of removal when there is no zero row in the matrix  $\tilde{M}_j$ . Because performing the Gauss-Jordan elimination in each step of removing single row is inefficient we use the same heuristic as desribed in the section 3.1.5. For better understanding we are providing the pseudocode of this removing as Algorithm 12.

Because this removing process removes only zero rows from the matrices  $\tilde{M}_j$  and no others rows are touched it does not influences the process of adding polynomials. Therefore this removing process is enabled by default and can not be disabled by any option from the automatic generator settings.

#### 3.2.4 Matrix partitioning

In the automatic generator the matrices we are dealing with are mostly sparse, so some more efficient techniques can be used to work with them. This will of course result into generation of more efficient and numerically stable solvers.

In this section we focus on how to speed up the Gauss-Jordan elimination of sparse matrices. We use the technique proposed in [11]. We observe that by permuting the rows and the columns of sparse matrices they can be transformed into matrices with block-diagonal structure known as singly-bordered block-diagonal (SBBD) form. Each diagonal block of the SBBD matrices forms an independent problem and therefore it can be independently eliminated. This speeds up the process of Gauss-Jordan elimination, because eliminating more smaller matrices is faster than eliminating one big matrix. If we divide the matrix into k independent blocks that contain comparable number of entries the speed up is approximately  $n^3 \to k \cdot \left(\frac{n}{k}\right)^3$ . Moreover the permutation matrices that transform matrices to the SBBD forms are precomputed during the solver generation process and therefore the resultant solver is working already with matrices in the SBBD forms and does not have to spend time to computing the permutation matrices again.

Let us say we want to eliminate matrix M. First of all we have remove columns that correspond to monomials from the basis B from the matrix, because these columns should not be permuted and eliminated. Then we need to compute the permutation matrix. To compute the permutation matrices we use the state of the art hypergraph partitioning tool PaToH [3] with settings to divide the matrix into two independent blocks. We do the permutations of rows a columns and get two diagonal blocks  $M_{11}$  and  $M_{22}$  and some coupling columns that can not be assigned to any of the diagonal blocks. Next we perform two independent eliminations of the blocks  $M_{11}$  and  $M_{22}$  and permute all rows of M to get the identity matrix in the left top corner. However we get non-eliminated submatrix in the right bottom corner of M. After eliminating this submatrix the rows above this submatrix are still not eliminated. If this is the last

#### Algorithm 12 Remove redundant polynomials

#### **Input:**

M a matrix representing a set of polynomials

 $\tilde{M}$  a matrix in a Row Echelon Form representing a set of polynomials

#### Output

M a matrix representing a set of polynomials

M a matrix in a Row Echelon Form representing a set of polynomials

```
1: toRemove \leftarrow number of zero rows of M
 2: nonZero \leftarrow number of non zero rows of \tilde{M}
 3: rows \leftarrow number of rows of M
 4: step \leftarrow \max\{|toRemove/4|, 1\}
 5: up \leftarrow 1
 6: filter \leftarrow \{1, 2, \dots, rows\}
 7: while toRemove \neq 0 do
         down \leftarrow up + step - 1
         if down > rows then
 9:
10:
             down \leftarrow rows
             step \leftarrow down - up + 1
11:
         end if
12:
         filter_{Old} \leftarrow filter
13:
         filter \leftarrow filter \setminus \{up, up + 1, \dots, down\}
14:
         M \leftarrow \text{Reduction to a Row Echelon Form of } M \text{ only with rows specified by } filter
15:
         if number of non zero rows of M < nonZero then
16:
             if step = 1 then
17:
                 up \leftarrow up + 1
18:
19:
             else
                 step \leftarrow \max\{|step/4|, 1\}
20:
             end if
21:
             filter \leftarrow filter_{Old}
22:
23:
         else
             toRemove \leftarrow number of zero rows of M
24:
             up \leftarrow down + 1
25:
             step \leftarrow \min\{2 \times step, toRemove\}
26:
         end if
27 \cdot
28: end while
29: return (M only with rows specified by filter, \tilde{M})
```

elimination in the solver we have to eliminate only the rows which we need to build the action matrix. If this is not the last elimination in the solver we have to eliminate them all.

**Example** Consider sparse matrix M of size  $119 \times 143$  as it is shown in Figure 3.2a. Columns 119 - 143 correspond to monomials from the monomial basis B. When we remove these columns we get rectangular matrix of size  $119 \times 119$  on which we execute the partitioning tool PaToH. After the permutation of the rows and columns we get the matrix in the SBBD form which can be seen in Figure 3.2b. We get two diagonal blocks  $M_{11}$  of size  $71 \times 30$  and  $M_{22}$  of size  $48 \times 38$  and 51 coupling columns which can not be assigned to any diagonal block. After two independent Gauss-Jordan eliminations

of the blocks  $M_{11}$  and  $M_{22}$  and row permutation we get the identity matrix in the left top corner, see Figure 3.2c. Now we have to perform the Gauss-Jordan elimination on submatrix of size  $51 \times 75$  in the right bottom corner. After this we get matrix as it is shown in Figure 3.2d. Now in the matrix lefts uneliminated submatrix of size  $68 \times 75$  in the right top corner. If this is the last elimination in the solver we do not have to eliminate it whole, but it is sufficient to eliminate only the rows we need to the constructing of the action matrix. If this is not the last elimination in the solver we have to eliminate the whole remaining uneliminated submatrix.

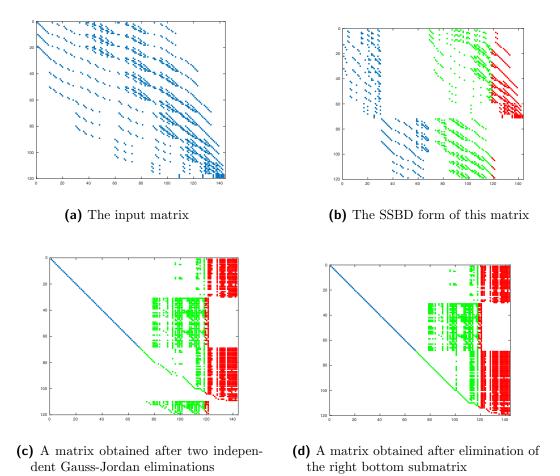

Figure 3.2 Example of the process of eliminating matrix using matrix partitioning. Colors: blue – two independent diagonal blocks, green – coupling columns, red – columns corresponding to the basis B

Since the matrix partitioning have not to be efficient for all minimal problems, it can be easily enabled or disabled in the automatic generator. By setting cfg.matrixPartitioning = 'all' the matrix partitioning is used to all Gauss-Jordan eliminations in the solver. If cfg.matrixPartitioning = 'last' is set the matrix partitioning is used only to the last Gauss-Jordan elimination in the solver. Matrix partitioning can totally disabled by setting cfg.matrixPartitioning = 'none'. At last we want to warn that the tool PaToH is not available under Windows OS so the matrix partitioning can not be used under this system.

#### 3.2.5 F4 strategy

Because polynomials in the polynomial generator module as it is described in section 3.1.4 are generated systematically, many of them are supefluous and therefore need not be generated. Since the automatic generator consists of independent modules we can replace the polynomial generator module by some better implementation.

In the chapter 2 we have described some of the state of the art techniques how polynomial systems can be solved. Therefore we can take over some of them and implement them into the automatic generator. In the section 2.2 we have understood the  $F_4$  [6] Algorithm so we have implemented this technique into the automatic generator.

Implementation of the  $F_4$  Algorithm in the automatic generator is the same as J. Ch. Faugère has described in [6] and we did in section 2.2. The only difference is that we need to track how the polynomials are constructing to be able to reconstruct the process in the solver generator module. In the  $F_4$  Algorithm, to be concrete in the function Symbolic Preprocessing, we are constructing matrices  $F_i$  from the selected pairs and polynomials from Gröbner basis G that are multiplied by a monomial. Polynomials that are constructed from the selected critical pairs are from G and multiplied by a monomial too. But polynomials in G are just the input polynomials or polynomials from  $F_i$  from all previous iterations. All these polynomials that are added into  $F_i$ are simplified by the function Simplify. That means that such a polynomial may be replaced by another polynomial taken from  $F_i$ . To sum up the matrix  $F_i$  is built from multiples of the input polynomials or polynomials from  $F_{1,...,i-1}$  and monomials. So to track the process of building the matrices  $F_i$  we just have to keep which polynomials from which matrices  $\tilde{F}_i$  (we can look at the input polynomials as if it is a matrix  $\tilde{F}_0$ ) multiplied with which monomials are used which can be easily done. In the end we have to recover how the matrix G was build, but this is the same case as reconstructing a matrix  $F_i$ , because the Gröbner basis G consists only of the input polynomials or polynomials from matrices  $F_i$ .

Unnecessary and redundant polynomials can be of course removed from the matrices  $F_i$  as we have described in sections 3.1.5 and 3.2.3. Moreover if nothing is added from the matrix  $\tilde{F}_i$  to the Gröbner basis G, i.e. the matrix  $\tilde{F}_i^+$  is empty, the matrix  $F_i$  can be removed totally. This leads to that in the resultant generated solver there will be no reduction to zero so much computation time can be saved. We are still working with sparse matrices so the matrix partitioning which is described in section 3.2.4 can be used to speed up the Gauss-Jordan eliminations.

By default this strategy is disabled in the automatic generator and the systematic polynomial generator as described in sections 3.1.4 and 3.2.2 is used. This is done by setting cfg.PolynomialsGenerator = 'systematic'. To enable the polynomial generator using the  $F_4$  strategy set cfg.PolynomialsGenerator = 'F4' in the automatic generator settings.

The key function in the  $F_4$  strategy is the Sel function which is descibed in section 2.2.6. While different Sel functions can be efficient for different minimal problems, it can be easily changed which function will be used. To use the normal strategy set cfg.PolynomialsGeneratorCfg.Sel =  $@F4_SelNormal$  and to select only one critical pair each time set cfg.PolynomialsGeneratorCfg.Sel =  $@F4_SelFirst$  in the automatic generator settings. This second function emulates the Buchberger Algorithm. Both this functions are stored in the folder generator/F4 and everybody can implement and use his own Sel function.
